# Severed Channels Probe Regulation of Gating of CFTR by its Cytoplasmic Domains 

László Csanády, Kim W. Chan, Donna Seto-Young, David C. Kopsco, Angus C. Nairn, and David C. Gadsbry

Applying the Schwarz Criterion to the Distribution of Open Times to Distinguish Between One or More Open States, in the Case of Only One Closed State
Consider a gating scheme with 1 closed state and any number of open states. Let the data consist of $M$ openings (without restricting generality, assume that the series starts and ends with closed events). The events list consists of the series of dwell times $t_{\mathrm{c}, 1}, t_{\mathrm{o}, 1}, t_{\mathrm{c}, 2}, t_{\mathrm{o}, 2}, \ldots t_{\mathrm{o}, \mathrm{M}}, t_{\mathrm{c}, \mathrm{M}+1}$. The likelihood of such a series of dwell times (Fredkin, D.R., M. Montal, and J.A. Rice. 1985. Identification of aggregated Markovian models: application to the nicotinic acetylcholine receptor. In Proceedings of the Berkeley Conference in Honor of Jerzy Neyman and Jack Kiefer. L.M. Le Cam and R.A. Ohlsen, editors. Wadsworth Publishing Co., Belmont, CA. 269-289) is:

$$
\begin{equation*}
L=\mathbf{p}_{\mathrm{c}}^{T}(0) \prod_{i=1}^{M}\left(e^{\mathbf{Q}_{\mathrm{cc}} t_{\mathrm{c}, i}} \mathbf{Q}_{\mathrm{co}} e^{\mathbf{Q}_{o \mathrm{o}} t_{\mathrm{o}, i}} \mathbf{Q}_{\mathrm{oc}}\right) e^{\mathbf{Q}_{\mathrm{cc} t_{\mathrm{c}}, M+1}} \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}, \text { where } \mathbf{p}_{\mathrm{c}}^{T}(0)=\frac{\mathbf{p}_{\mathrm{o}}^{T}(\infty) \mathbf{Q}_{\mathrm{oc}}}{\mathbf{p}_{\mathrm{o}}^{T}(\infty) \mathbf{Q}_{\mathrm{oc}} \mathbf{1}_{\mathrm{c}}}, \tag{S1}
\end{equation*}
$$

where $\mathbf{Q}_{\mathrm{cc}}, \mathbf{Q}_{\mathrm{oo}}, \mathbf{Q}_{\mathrm{c} \text { o }}$, and $\mathbf{Q}_{\mathrm{oc}}$ are submatrices of the state matrix $\mathbf{Q}$, and $\mathbf{p}_{\mathrm{o}}^{T}(\infty)$ and $\mathbf{p}_{\mathrm{c}}^{T}(\infty)$ (see below) are row vectors of steady state occupancy probabilities, and $\mathbf{1}_{o}$ and $\mathbf{1}_{c}$ summation vectors, for the sets of closed and open states, respectively.

Because there is only one closed state, the following identities apply:

$$
\begin{equation*}
\mathbf{Q}_{\mathrm{co}}=\mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}} \mathbf{p}_{\mathrm{o}}^{T}(0) \text {, where } \mathbf{p}_{\mathrm{o}}^{T}(0)=\frac{\mathbf{p}_{\mathrm{c}}^{T}(\infty) \mathbf{Q}_{\mathrm{co}}}{\mathbf{p}_{\mathrm{c}}^{T}(\infty) \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}} . \tag{a}
\end{equation*}
$$

This is because $\mathbf{p}_{\mathrm{c}}^{T}(\infty)$ is simply a scalar number, and so:

$$
\begin{gather*}
\mathbf{p}_{\mathrm{o}}^{T}(0)=\frac{\mathbf{Q}_{\mathrm{co}}}{\mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}} \text { and } \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}} \mathbf{p}_{\mathrm{o}}^{T}(0)=\frac{\left(\mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}\right) \mathbf{Q}_{\mathrm{co}}}{\mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}}=\mathbf{Q}_{\mathrm{co}} . \\
\mathbf{Q}_{\mathrm{oc}}=\mathbf{Q}_{\mathrm{oc}} \mathbf{1}_{\mathrm{c}} \mathbf{p}_{\mathrm{c}}^{T}(0),\left[\text { since } \mathbf{1}_{\mathrm{c}} \mathbf{p}_{\mathrm{c}}^{T}(0)\right. \text { is simply the (scalar) number 1]. } \tag{b}
\end{gather*}
$$

Substituting from Eqs. a and b into Eq. S1, the likelihood of the whole time series becomes

$$
\begin{align*}
L & =\mathbf{p}_{\mathrm{c}}^{T}(0) \prod_{i=1}^{M}\left[e^{\mathbf{Q}_{\mathrm{cc}} t_{\mathrm{c}, i}} \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}} \mathbf{p}_{\mathrm{o}}^{T}(0) e^{\mathbf{Q}_{o o} t_{0, i}} \mathbf{Q}_{\mathrm{oc}} \mathbf{1}_{\mathrm{c}} \mathbf{p}_{\mathrm{c}}^{T}(0)\right] e^{\mathbf{Q}_{\mathrm{cc}} t_{\mathrm{c}, M+1}} \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}} \\
& =\prod_{i=1}^{M}\left\{\left[\mathbf{p}_{\mathrm{c}}^{T}(0) e^{\mathbf{Q}_{\mathrm{cc}} t_{\mathrm{c}, i}} \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}\right]\left[\mathbf{p}_{\mathrm{o}}^{T}(0) e^{\mathbf{Q}_{o o} t_{o, i}} \mathbf{Q}_{\mathrm{oc}} \mathbf{1}_{\mathrm{c}}\right]\right\}\left[\mathbf{p}_{\mathrm{c}}^{T}(0) e^{\mathbf{Q}_{\mathrm{cc}} t_{\mathrm{c}, M+1}} \mathbf{Q}_{\mathrm{co}} \mathbf{1}_{\mathrm{o}}\right] \\
& =\left[\prod_{i=1}^{M+1} p d f_{\mathrm{c}}\left(t_{\mathrm{c}, i}\right)\right] \cdot\left[\prod_{i=1}^{M} p d f_{\mathrm{o}}\left(t_{\mathrm{o}, i}\right)\right] . \tag{S2}
\end{align*}
$$

The $\log$ of the likelihood, $L L=\ln (L)$ then becomes:

$$
\begin{equation*}
L L=\left\{\sum_{i=1}^{M+1} \ln \left[p d f_{\mathrm{c}}\left(t_{\mathrm{c}, \mathrm{i}}\right)\right]\right\}+\left\{\sum_{i=1}^{M} \ln \left[p d f_{\mathrm{o}}\left(t_{\mathrm{o}, \mathrm{i}}\right)\right]\right\}=L L_{\mathrm{c}}\left(\mathbf{t}_{\mathrm{c}}\right)+L L_{\mathrm{o}}\left(\mathbf{t}_{\mathrm{o}}\right) \tag{S3}
\end{equation*}
$$

1 J. Gen. Physiol. © The Rockefeller University Press • 0022-1295
Volume 116 September 2000
http://www.jgp.org/cgi/content/full/116/3/477/DC1
where $\mathbf{t}_{c}$ and $\mathbf{t}_{\mathrm{o}}$ represent the separated vectors of closed and open dwell times, respectively. Hence, the log likelihood of the whole time series separates into the sum of the log likelihoods of the closed and open times. Moreover, the latter two log likelihoods depend on disjoint subsets of parameters: let $r_{\text {co }}$ denote the sum of all rates leading from the unique closed state to all adjacent open states. $L L_{\mathrm{o}}$ does not depend on the size of $r_{\mathrm{co}}$, while $L L_{\mathrm{c}}$ depends solely on $r_{\text {со }}$ through:

$$
L L_{\mathrm{c}}=\sum_{i=1}^{M+1} \ln \left(r_{\mathrm{co}} e^{-r_{\mathrm{co}} t_{\mathrm{c}, \mathrm{i}}}\right)
$$

If $\Theta$ denotes the gating scheme with its rate constants, then optimization of $L L$ with respect to $\Theta$ can be achieved by separately optimizing $L L_{\mathrm{c}}$ with respect to $r_{\mathrm{co}}$, and $L L_{\mathrm{o}}$ with respect to $\Theta \cap \overline{\left\{r_{\mathrm{co}}\right\}}$. Moreover, $L L_{\mathrm{c}}$ at the peak is the same for any two schemes with one closed state: $L L_{c}\left(\mathbf{t}_{c} \mid \Theta_{2}\right)=L L_{c}\left(\mathbf{t}_{c} \mid \Theta_{1}\right)$, from which:

$$
\begin{equation*}
\Delta L L=L L\left(\mathbf{t} \mid \Theta_{2}\right)-L L\left(\mathbf{t} \mid \Theta_{1}\right)=L L_{\mathrm{o}}\left(\mathbf{t}_{\mathrm{o}} \mid \Theta_{2}\right)-L L_{\mathrm{o}}\left(\mathbf{t}_{\mathrm{o}} \mid \Theta_{1}\right)=\Delta L L_{\mathrm{o}} . \tag{S4}
\end{equation*}
$$

Thus, $\Delta L L_{\mathrm{o}}$, the log of the likelihood ratio for $M$ open times, corresponds to $\Delta L L$ for a time series of $2 M(+1)$ events for any pair of schemes that both have one closed state.

Reconstruction of the Time Sequence of Unlocking Events

Task. $N$ channels, $N_{\mathrm{o}}$ locked initially, reconstruct time sequence $t_{N_{\mathrm{o}}}<t_{N_{\mathrm{o}}-1}<\ldots<t_{k}<\ldots t_{1}$ of unlocking events.
Strategy. The $k$ th channel is considered to become unlocked at the start of a gap to lower conductance levels of duration exceeding a defined cutoff $\delta_{k}$.

Problem. How to choose a cutoff $\delta_{k}$ separately for each conductance level, such that the probabilities of assigning a particular unlocking event too early or too late are equal?

Single-channel model. Consider a patch with several (5-20) channels, each of which can transit from a closed state $(C)$ to either a relatively short-lived open state $(O)$, or a very long-lived conducting state ( $L$, for "locked open"). State $L$ also communicates with a brief blocked ( $B$, nonconducting) state. At steady state, the rates are suddenly changed such that rate $r_{\mathrm{CL}}=0$, and $r_{\mathrm{CO}}$ becomes extremely small. The system can now be described by the scheme:

$$
\left[B \underset{r_{\mathrm{LB}}}{\stackrel{r_{\mathrm{BL}}}{\leftrightarrows}} L \stackrel{r_{\mathrm{LC}}}{\rightarrow} C \underset{r_{\mathrm{OC}}}{r_{\mathrm{CO}}} O\right] \times N,
$$

where, initially, $N_{\mathrm{o}}$ channels are in $L$, and $N-N_{\mathrm{o}}$ in $C$. First, obtain estimates of $r_{\mathrm{LB}}$ and $r_{\mathrm{BL}}$ from sections of record with just one channel locked ( $r_{\mathrm{LB}} \approx 3 \mathrm{~s}^{-1}, r_{\mathrm{BL}} \approx 13 \mathrm{~s}^{-1}$ ). Second, obtain estimate of apparent reopening rate $r_{\mathrm{CO}}$ after all channels are unlocked ( $r_{\mathrm{CO}}<0.005 \mathrm{~s}^{-1}$ typically).

Macroscopic model. Consider time interval after $(k+1)$ th channel has unlocked, but $k$ th channel has not unlocked yet. During this time interval, describe macroscopic system by simplified two-dimensional macroscopic state vector $\left(n_{\mathrm{S}}, n_{\mathrm{A}}\right)$, corresponding to the number of shut (closed or blocked) and active (locked or open) channels, respectively $\left(n_{\mathrm{S}}+n_{\mathrm{A}}=N\right)$. Hence, the number of macroscopic states is $N+1$. Index macroscopic states in increasing order of $n_{\mathrm{A}}$, build state-matrix $\mathbf{Q}(k)$. Neglecting the effect of channel reopening within flickery gaps ( $r_{\mathrm{CO}} \ll r_{\mathrm{BL}}$ ), $\mathbf{Q}(\mathrm{k})$ simplifies to:

Define $l(k)$ as the set of macroscopic states indexed from 0 to $k-1$ (i.e., $n_{\mathrm{A}}=0,1, \ldots$ or $k-1$ ). Similarly, define $h(k)$ $=\{k, k+1, \ldots N\}, \hat{l}(k)=\{0,1, \ldots k\}, \hat{h}(k)=\{k+1, \ldots N\}$, and partition $\mathbf{Q}$ correspondingly.

Errors. $P_{1}(\mathrm{k})=P$ (unlocking of $k$ th channel assigned too late) $=P$ [leaving from $\hat{l}(k-1)$ to $\hat{h}(k-1)$ occurs between $t_{\mathrm{k}}$ and $\left.t_{\mathrm{k}}+\delta_{\mathrm{k}}\right]=$

$$
1-[0, \ldots, 0,1] e^{\mathbf{Q}_{\hat{l}}(k-1) \delta_{k}} \mathbf{1}_{\hat{l}(k-1)}
$$

$P_{2}(\mathrm{k})=P$ (unlocking of $k^{\prime}$ th channel assigned too early) $=1-P$ (unlocking of $k^{\prime}$ th channel is not assigned too early) $=1-P$ (all leavings from $h(k)$ to $l(k)$ between time $t_{\mathrm{k}+1}$ and $t_{\mathrm{k}}$ are shorter than $\left.\delta_{\mathrm{k}}\right]=1-\{P$ [a leaving from $h(k)$ to $l(k)$ between time $t_{\mathrm{k}+1}$ and $t_{\mathrm{k}}$ is shorter than $\left.\left.\delta_{\mathrm{k}}\right]\right\}^{v}=$

$$
1-\left\{1-[0, \ldots, 0,1] e^{\mathbf{Q}_{l l}(k) \delta_{k}} \mathbf{1}_{l(k)}\right\}^{v}
$$

where $v$ is the expected number of leavings from $h(k)$ to $l(k)$ between time $t_{\mathrm{k}+1}$ and $t_{\mathrm{k}}$. Both $P_{1}(\mathrm{k})$ and $P_{2}(\mathrm{k})$ are functions of the cutoff time $\delta_{\mathrm{k}}$. Search for $\delta_{\mathrm{k}}$ such that calculated $P_{1}(\mathrm{k})$ equals $P_{2}(\mathrm{k})$. The total probability of misassigning $t_{\mathrm{k}}$ is $P(\mathrm{k})=P_{1}(\mathrm{k})+P_{2}(\mathrm{k})$.

Iteration. $v \approx r_{\mathrm{LB}} / r_{\mathrm{LC}}$, but $r_{\mathrm{LC}}$ is not known a priori. Solve by iteration: in the first round, set $v^{(1)}=1$, calculate $\delta_{k}^{(1)}$ (as above), and then find $t_{k}^{(1)}$ for each $k=N_{\mathrm{o}}, \ldots 1$. Estimate $r_{\mathrm{LC}}$ by

$$
r_{\mathrm{LC}}^{(1)}=N_{\mathrm{o}} / \sum_{k=1}^{N_{\mathrm{o}}} t_{k}^{(1)}
$$

Repeat by setting $v^{(i)}=\left(r_{\mathrm{LB}} / r_{\mathrm{LC}}^{(i-1)}\right)$. Stop iteration if $t_{k}^{(i)}=t_{k}^{(i-1)}$ for all $k=N_{\mathrm{o}}, \ldots 1$.
Results. Time sequence $t_{N_{\mathrm{o}}}<t_{N_{\mathrm{o}}-1}<\ldots<t_{k}<\ldots t_{1}$ of unlocking events, error estimate $P(\mathrm{k})$ for each conductance level, estimate for $r_{\text {LC }}$ (unlocking rate, estimated from the average wait time for unlocking).

## How Applicable Is a Closed-Open-Blocked Fit to Scheme I?

A valid concern is that Scheme I (itself a four-state scheme), extended by short-lived ("flickery") closed states, is not readily seen to reduce to a simple three-state, Closed-Open-Blocked (C-O-B) scheme. How do the burst durations determined from the multichannel C-O-B fit compare to the fits to the distributions of single-channel burst durations (particularly for constructs $835+837$, cut- $\Delta \mathrm{R}$, and Flag-cut- $\Delta \mathrm{R}$, which showed two components in the distributions of burst durations)? This is justified as follows. The C-O-B fit merely separates out short flickery closures (i.e., it is the multichannel implementation of single-channel burst analysis), and it works because the mean duration of flickery closures $(\sim 10 \mathrm{~ms})$ is $>100$-fold shorter than that of interburst closures, while the length of the mean burst durations varied only less than fourfold. So, for the purpose of separating flickery from interburst closures, pooling the open states is certainly justifiable. This assertion is supported by the good agreement between $\tau_{\mathrm{b}}$ extracted from multichannel fits (see Table I in text), and the means of the distributions of bursts obtained from isolated openings (Fig. 8). But since we were also concerned about the validity of this approach, we tested it extensively on simulated
traces (as briefly mentioned in the discussion). As an example, we took Scheme I with rates $\left(\mathrm{s}^{-1}\right) k_{1}=0.7, k_{-1}=$ $3.5, k_{2}=0.3, k_{-2}=0.2, k_{3}=0.9$, a typical set for cut- $\Delta \mathrm{R}$ channels (rates between $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ were set to simulate saturating [ATP], $r_{\mathrm{C} 1, \mathrm{C} 2}=10 \mathrm{~s}^{-1}, r_{\mathrm{C} 2, \mathrm{C} 1}=0.1 \mathrm{~s}^{-1}$ ). We next extended this scheme with blocked states $\mathrm{B}_{1}$ and $\mathrm{B}_{2}$, communicating with $\mathrm{O}_{1}$ and $\mathrm{O}_{2}$, respectively, and set $r_{\mathrm{O} 1, \mathrm{~B} 1}=r_{\mathrm{O} 2, \mathrm{~B} 2}=3 \mathrm{~s}^{-1}, r_{\mathrm{B} 1, \mathrm{O} 1}=r_{\mathrm{B} 2, \mathrm{O} 2}=100 \mathrm{~s}^{-1}$, to elicit flickery closures with characteristics typical of those seen in our recordings. We then simulated a 3-min segment with four channels obeying this extended six-state scheme, and repeated the simulation five times with the same rate constants, but a different random seed value. The five traces were then idealized, and fitted separately using the C-O-B scheme, as described in methods (compare Csanády, 2000), with $t_{\mathrm{d}}=4 \mathrm{~ms}$. The mean ( $\pm$ SEM) estimates from the five fits were $r_{\mathrm{CO}}=0.68 \pm 0.02 \mathrm{~s}^{-1}, r_{\mathrm{OC}}=3.0 \pm 0.2 \mathrm{~s}^{-1}, r_{\mathrm{OB}}=2.7 \pm 0.1 \mathrm{~s}^{-1}, r_{\mathrm{BO}}=94 \pm 2 \mathrm{~s}^{-1}$, predicting mean burst and interburst durations of $\tau_{\mathrm{b}}=353 \pm 26 \mathrm{~ms}$, and $\tau_{\mathrm{ib}}=1,485 \pm 41 \mathrm{~ms}$, respectively; the latter values being closely similar to the $\tau_{\mathrm{b}}=340 \mathrm{~ms}$ and $\tau_{\mathrm{ib}}=1,543 \mathrm{~ms}$ predicted by the model ( $\tau_{\mathrm{b}}$ is given by Eq. 1 of text, $\tau_{\mathrm{ib}} \approx 1 / k_{1}$ ). This is despite the fact that the burst duration distribution for this scheme is characterized by two clearly discernible components with parameters $\tau_{\mathrm{sh}}=262 \mathrm{~ms}, \tau_{1}=928 \mathrm{~ms}, a_{\mathrm{sh}}=0.88, a_{1}=0.12$.

## Derivation of Observable Parameters for Scheme I

Mean open time (burst duration). The mean open time (see $\tau_{\mathrm{b}}$ in text) is the weighted average of the durations of various types of openings, each weighted by its fractional occurrence. Openings either close from $\mathrm{O}_{1}$, after venturing $m$ times to $\mathrm{O}_{2}, m=0, \ldots \infty$, "type $1_{\mathrm{m}}$;" or from $\mathrm{O}_{2}$, upon entering $\mathrm{O}_{2}$ the $m^{\text {th }}$ time, $m=1, \ldots \infty$, "type $2_{\mathrm{m}}$." The mean durations of individual dwells at $\mathrm{O}_{1}$ or $\mathrm{O}_{2}$ are $\tau_{\mathrm{O} 1}=1 /\left(k_{-1}+k_{2}\right)$ and $\tau_{\mathrm{O} 2}=1 /\left(k_{-2}+k_{3}\right)$, respectively. Let $\pi_{-1}$ be the probability that a channel in $\mathrm{O}_{1}$ will next exit to $\mathrm{C}_{1}$, and $\pi_{2}$ the probability that it will next exit to $\mathrm{O}_{2}$. Similarly, $\pi_{-2}$ and $\pi_{3}$ denote probabilities that a channel in $\mathrm{O}_{2}$ next exits to $\mathrm{O}_{1}$ or $\mathrm{C}_{1}$, respectively. Hence, $\pi_{-1}=k_{-1} /\left(k_{-1}+k_{2}\right)$, $\pi_{-2}=k_{-2} /\left(k_{-2}+k_{3}\right)$, and $\pi_{3}=k_{3} /\left(k_{-2}+k_{3}\right)$. The mean duration of a type $1_{\mathrm{m}}$ opening is $(m+1) \cdot \tau_{\mathrm{O} 1}+m \cdot \tau_{\mathrm{O} 2}$, with fractional occurrence $\pi_{2}^{m} \pi_{-2}^{m} \pi_{-1}$, while type $2_{\mathrm{m}}$ openings last for $m \cdot\left(\tau_{\mathrm{O} 1}+\tau_{\mathrm{O} 2}\right)$, and occur with $\pi_{2}^{m} \pi_{-2}^{m-1} \pi_{3}$ probability. Hence,

$$
\begin{gathered}
\tau_{b}=\sum_{m=0}^{\infty} \pi_{2}^{m} \pi_{-2}^{m} \pi_{-1}\left[(m+1) \cdot \tau_{\mathrm{O} 1}+m \cdot \tau_{\mathrm{O} 2}\right]+\sum_{m=1}^{\infty} \pi_{2}^{m} \pi_{-2}^{m-1} \pi_{3}\left[m \cdot\left(\tau_{\mathrm{O} 1}+\tau_{\mathrm{O} 2}\right)\right] \\
=\left(\pi_{-1}+\pi_{3} / \pi_{-2}\right) \cdot\left(\tau_{\mathrm{O} 1}+\tau_{\mathrm{O} 2}\right) \cdot \sum_{m=0}^{\infty} m \cdot\left(\pi_{2} \pi_{-2}\right)^{m}+\pi_{-1} \cdot \tau_{\mathrm{O} 1} \cdot \sum_{m=0}^{\infty}\left(\pi_{2} \pi_{-2}\right)^{m}
\end{gathered}
$$

from which, using identities

$$
\begin{gather*}
\sum_{m=0}^{\infty} m \cdot q^{m}=q /(1-q)^{2} \text { and } \sum_{m=0}^{\infty} q^{m}=q /(1-q) \text { for } q<1: \\
\tau_{\mathrm{b}}=\left(\pi_{-1}+\pi_{3} / \pi_{-2}\right) \cdot\left(\tau_{\mathrm{O} 1}+\tau_{\mathrm{O} 2}\right) \cdot \pi_{2} \pi_{-2} /\left(1-\pi_{2} \pi_{-2}\right)^{2}+\pi_{-1} \cdot \tau_{\mathrm{O} 1} /\left(1-\pi_{2} \pi_{-2}\right) \tag{S5}
\end{gather*}
$$

Substituting for $\pi_{-1}, \pi_{2}, \pi_{-2}, \pi_{3}, \tau_{\mathrm{O} 1}$, and $\tau_{\mathrm{O} 2}$ from the rates, Eq. S5 reduces to Eq. 1 in the text.
Survivor function of open times (burst durations). Numbering the states of Scheme I in the order $\mathrm{C}_{1}, \mathrm{C}_{2}, \mathrm{O}_{1}, \mathrm{O}_{2}$, the $\mathbf{Q}$ matrix of the system is:

in particular, the submatrix of the set of states $\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}$ is:

$$
\mathbf{Q}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}=\left|\begin{array}{cc}
-\left(k_{-1}+k_{2}\right) & k_{2} \\
k_{-2} & -\left(k_{3}+k_{-2}\right)
\end{array}\right|
$$

The Eigenvalues of the submatrix are:

$$
\lambda_{ \pm}=\frac{-\left(k_{-1}+k_{2}+k_{-2}+k_{3}\right) \pm \sqrt{D}}{2}
$$

where $D=\left(k_{-1}+k_{2}+k_{-2}+k_{3}\right)^{2}-4\left(k_{-1} k_{3}+k_{-1} k_{-2}+k_{2} k_{3}\right)$. The exponential of the submatrix is:

$$
\begin{aligned}
& e^{Q_{\left.\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}, \mathrm{O}_{1}, \mathrm{O}_{2}\right\}^{\prime} t}} \\
& =\left|\begin{array}{cc}
\frac{\left(e^{\lambda_{+} t}+e^{\lambda_{-} t}\right)}{2}-\frac{k_{-1}+k_{2}-k_{-2}-k_{3}}{2 \sqrt{D}} \cdot\left(e^{\lambda_{+} t}-e^{\lambda_{-} t}\right) & \frac{k_{2}}{\sqrt{D}} \cdot\left(e^{\lambda_{+} t}-e^{\lambda_{-} t}\right) \\
\frac{k_{-2}}{\sqrt{D}} \cdot\left(e^{\lambda_{+} t}-e^{\lambda_{-} t}\right)
\end{array}\right|
\end{aligned}
$$

The survivor function of $\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}$ is:

$$
\operatorname{surv}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}(t)=\mathbf{p}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}(0)^{\mathrm{T}} e^{\mathbf{Q}_{\left.\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\} \mathrm{O}_{1}, \mathrm{O}_{2}\right\}^{t} t}} \mathbf{1}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}
$$

(see Csanády, 2000), where $\mathbf{p}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}(0)^{\mathrm{T}}=[1,0]$ (since all openings start in $\mathrm{O}_{1}$ ); i.e., the survivor function simplifies to the sum of the first row of the submatrix:

$$
\begin{equation*}
\operatorname{surv}_{\left\{\mathrm{O}_{1}, \mathrm{O}_{2}\right\}}(t)=\frac{\sqrt{D}-k_{2}-k_{-2}-k_{3}+k_{-1}}{2 \sqrt{D}} \cdot e^{\lambda_{-} t}+\frac{\sqrt{D}+k_{2}+k_{-2}+k_{3}-k_{-1}}{2 \sqrt{D}} \cdot e^{\lambda_{+} t} \tag{S6}
\end{equation*}
$$

The coefficient of the first term and $-\lambda_{-}^{-1}$ give $a_{\text {sh }}$ and $\tau_{\text {sh }}$, respectively (Eqs. 2 and 3 in text), while the second coefficient and $-\lambda_{+}^{-1}$ yield $a_{1}$ and $\tau_{1}$ (Eq. 4 in text). As a check, the mean of the above distribution, $<t>=a_{\text {sh }} \tau_{\text {sh }}+a_{1} \tau_{1}$, is identical to $\tau_{\mathrm{b}}$ in Eq. S5 (Eq. 1 in text).

Time course of unlocking from AMPPNP-mediated lock. The predicted time course of unlocking is obtained by solving the differential equation describing scheme

$$
\mathrm{O}_{2} \xrightarrow{k_{-2}} \mathrm{O}_{1} \xrightarrow{k_{-1}} \mathrm{C}_{1},
$$

with initial condition $o_{1}(0)=k_{-2} /\left(k_{2}+k_{-2}\right), o_{2}(0)=k_{2} /\left(k_{2}+k_{-2}\right)$. The vector solution of equation:

$$
\frac{d}{d t}\left[\begin{array}{l}
o_{1} \\
o_{2}
\end{array}\right](t)=\left[\begin{array}{cc}
-k_{-1} & k_{-2} \\
0 & -k_{-2}
\end{array}\right]\left[\begin{array}{l}
o_{1} \\
o_{2}
\end{array}\right](t),
$$

with the above initial condition is:

$$
\left[\begin{array}{l}
o_{1}  \tag{S7}\\
o_{2}
\end{array}\right](t)=\frac{k_{-2}}{k_{2}+k_{-2}} \cdot\left[\begin{array}{c}
1-\frac{k_{2}}{k_{-1}-k_{-2}} \\
0
\end{array}\right] \cdot e^{-k_{-1} t}+\frac{k_{2}}{k_{2}+k_{-2}} \cdot\left[\begin{array}{c}
\frac{k_{-2}}{k_{-1}-k_{-2}} \\
1
\end{array}\right] \cdot e^{-k_{-2} t},
$$

from which the time course, obtained as $o(t)=o_{1}(t)+o_{2}(t)$, contains a slow component with time constant $1 / k_{-2}$ (see Eq. 5 in text) and fractional amplitude $\left[k_{2} /\left(k_{2}+k_{-2}\right)\right] \cdot\left[k_{-1} /\left(k_{-1}-k_{-2}\right)\right]$ (see Eq. 6 in text); as well as a fast component with time constant $1 / k_{-1}$ and complementary fractional amplitude.
